An Analysis of Retail and Service Sector Count Data:
Identification of Market Potential for Wisconsin Counties

Steven Deller, Matt Kures and Bill Ryan

Abstract

The objective of this applied research project is to use Wisconsin county sales tax data to identify the strengths and weaknesses of selected retail and service sectors. Using "count" data on the number of businesses that report taxable sales we apply regression analysis to develop an estimate of the expected number of firms in the county. By comparing the observed and expected number of firms we can identify strengths and weaknesses. Through the regression analysis we can also identify which socioeconomic characteristics are associated with which types of retail and service firms. The method that we offer we refer to as Firm Count Analysis (FCA) and can be viewed as a complement to Trade Area Analysis (TAA) and the analysis of sales data.

Introduction

One of the most common requests of community economic development practitioners is to develop a market analysis of the relative strengths and weaknesses of the local retail and service market. Traditionally these requests are from communities that are interested in downtown redevelopment or the expansion of their economic development policies beyond the traditional focus on basic industries.[1] The range of market analysis tools at the disposal of the practitioner is vast and varies from the simple to the complex.[2]

The purpose of this applied research project is to introduce a slightly different approach, an approach that has seen significant exposure in the academic literature but only limited application in practice. The approach builds on the notion of thresholds as discussed by McConnon (1989) and Deller and Ryan (1996). Demand threshold is defined as the minimum market size required to support a particular type of retail or service business and still yield an acceptable rate of return for the business owner (Berry and Garrison 1958a and 1958b; Foust and Pickett 1974; Shaffer, Deller and Marcouiller 2004). The concept is based on the internal economy of the firm and the characteristics of consumer demand. Demand thresholds are usually measured in terms of the population required to support one or more firms of a certain type.

[1] A "basic" industry traditionally focuses on producing goods or services that are for export out of the community. These include agricultural, mining, forestry and manufacturing goods and large service industries such as insurance processing companies.

[2] For a more detailed discussion of alternative methods to analyze local retail and service markets, see the UW-Extension program entitled "Downtown and Business District Market Analysis" by Bill Ryan and Matt Kures at http://www.uwex.edu/ces/cced/dma/.

The approach adopted in this applied study builds on threshold analysis by examining the underlying structure of demand for a range of different types of retail and service firms. Rather than narrowly focus on population threshold estimates, such as the number of people required to support a barber shop, we want to expand the analysis to predict the number of firms of a certain type. Once we have a prediction of the number of firms the community should have, given its socioeconomic characteristics, we can compare the predicted to the observed. If the number of observed is greater than the predicted level, then we can reasonably conclude that this sector is a strength for the community. If the observed level is less than the predicted level, then the community does not have as many firms as expected, and the sector could be deemed a weakness. From a community economic development perspective, the community can build on its strengths and further examine its weaknesses for development potential. We refer to this approach as Firm Count Analysis (FCA) and can be viewed as a complement to the more traditional Trade Area Analysis (TAA) where sales data are used to compute Pull Factors and measures of Surplus/Leakage.

One comparable area of work that we are building upon is industry targeting. Today the concept of targeting industry is dominated by the ideas of industry clustering as advanced by Michael Porter (1990). The idea behind business clustering is that firms are integrated both horizontally and vertically across and within industry types.[3] Communities, or more correctly regions, should identify industries where they have a comparative advantage and build on those industries along with those integrated industries. But the "Porter Approach" is but a natural progression of a large family of industry targeting modeling systems.

Using classical location theory of the firm there is a rich and extensive empirical literature that has examined factors that influence the location of firms. The question addressed is what is the probability of a firm of a certain type (i.e., within a certain industry type) being located in a community with a certain set of socioeconomic characteristics. Firms that have high probabilities are then targeted for recruitment.

Unfortunately, the vast majority of this literature has focused on manufacturing location decisions. The bias in the empirical literature towards manufacturing is partially a reflection of the bias in community economic development policy towards "smoke stack chasing" and the narrow thinking

[3] It is important to distinguish between industry clustering in the spirit of Porter that can occur at a larger geographic scale and retail clustering which can occur at a shopping district level or at the shopping center level. While both forms of clustering recognize horizontal and vertical integration, they have the potential to occur at dramatically different geographic scales.

that economic growth was equated with attracting manufacturing firms. These modeling efforts have resulted in a number of Extension based educational programs such as the work of Good and Hastings (1989) with their models of the Northeastern U.S., Leatherman, Howard and Kastens (2002) and their models of the Great Plains and Nagy, Orfert and Skotheim's (undated) work with Canadian regions.

In this applied research project we merge elements from the threshold approach used in looking at retail and service firms, and classical location theory used in looking at manufacturing firms. In the end we will have isolated a handful of socioeconomic characteristics that help explain the presence of retail and service firms and then identify if the community (county) is performing above or below expectations, as defined by the statistical models.

Beyond these introductory comments, our study is composed of four parts. In the next section we outline the empirical methods and provide a bit more background on the theoretical foundations for the modeling approach. We then review the empirical findings in terms of the collection of socioeconomic variables that help us better understand the pattern of observed retail and service firm levels. Next we look at the patterns of strengths and weaknesses where we compare the observed to predicted number of firms. We close by discussing some of the key findings, limitations, and future research efforts.

Methods and Model

As briefly described in our introductory comments, firm location theory has provided us with a rigorous framework for thinking about the forces behind why firms locate or start in one community, but not another. Firm location theory also provides a collection of empirical tools to help target specific types of firms for development. The most general approach to think about firm location is in the neoclassical framework of profit maximization (Shaffer, Deller and Marcouiller 2004). Firms select a location in such a way as to maximize the demand (revenues) for the good or service that they offer for sale while simultaneously minimizing the costs of transporting inputs to the firm and outputs to customers.

Historically, researchers who have studied firm location decisions have broken the profit maximization problem down into its two respective parts. The logic is that firms that are production oriented (e.g., manufacturing) tend to be more concerned with the costs of transportation and the location decision tends to not affect the demand for the good or service. In other words, researchers assumed that for many types of firms, transportation costs drove the decision and the revenue (demand) side could be ignored. The empirical studies that fall into this camp look at items like tax structures, supply of infrastructure, and labor market conditions to

name a few. This literature has provided the academic backbone to firm attraction policies such as tax incentives and investments in transportation infrastructure.

There is another set of firms, predominately retail and personal and business service firms, which is assumed to be more focused on the revenue or demand side of the profit maximization question. Here the firm locates relative to its potential customers determines demand and hence profits. Studies that are focused on these types of firms are concerned with the socioeconomic characteristics of the community in predicting retail and service sales levels. Some of these studies have focused on trying to explain levels of sales/revenue (e.g., Deller and Chicoine 1989; Chrisman 1985; Henderson 1990) while others have focused more narrowly on threshold estimates (e.g., Salyards and Leitner 1981; Schular and Leistritz 1991; Deller and Harris 1993; Harris, Chakraborty, Xiao and Narayanan 1996).

For this study we build on the market threshold approach by broadening the focus beyond simple population estimates to include the expansive factors considered in broader firm location studies. In practice, the empirical models often take the form:

$$N = \alpha + \beta P + \sum_{i=1\ldots m} \gamma_i X_i + \varepsilon. \qquad (1)$$

Here N is the number of firms of a particular type (e.g., grocery store, barber shop, etc.), P is a measure of the size of the community, usually population and X is a set of m socioeconomic variables such as income, age profiles, education levels among others. The parameters α, β and γ are to be estimated and ε is the regression error term.

A formulation of a simple regression model as outlined in equation (1) allows the researcher to look at three separate items. The first is perhaps the most academic and is concerned with the parameters α, β and γ in the traditional sense of hypothesis testing. For example, do age profiles influence the number of a particular type of firm and if so, in what way? The second is traditional threshold analysis which focuses on the relationship between the number of firms of a particular type and the measure of community size, again traditionally population. For illustrative purposes, assume that equation (1) can be expressed solely in terms of the intercept term (α) and size (βP). By slightly rearranging the estimated parameters (i.e., $\hat{\alpha}, \hat{\beta}$) we have:

$$N = \hat{\alpha} + \hat{\beta} P \rightarrow \frac{N - \hat{\alpha}}{\hat{\beta}} = P^C \qquad (2)$$

and P^C is the critical value, or population required to support a given number of establishments. The third item is in the spirit of the industry targeting work of Goode, Hastings, Leatherman and Olfret where we look at the expected value of dependent variable, or in this case N, and this is the approach explored here.

Once we apply the appropriate estimation method to the model outline in equation (1) we have a statistical model that can be expressed as:

$$\hat{N} = \hat{\alpha} + \hat{\beta} P + \sum_{i=1\ldots m} \hat{\gamma}_i X_i . \qquad (3)$$

The difference between equation (1) and (2) is that equation (1) represents the "true" relationship between the right-hand-side variables and the number of firms (N). We approximate that true relationship using statistical methods, the results of which are expressed in equation (3). The error term (ε) captures errors in the data (sometimes called noise such as errors in the measurement of the variables), in the estimation (statistical) tools, the specification of the model itself, and the underlying theory. By entering the right-hand-side data for a given community, one can derive an estimate of the expected value of the number of firms ($\hat{N}$). The value of the error term is derived as $\hat{\varepsilon} = N - \hat{N}$ and can be used to assess the strengths and weaknesses of the retail and service market of the community. If $N > \hat{N} \Rightarrow \hat{\varepsilon} > 0$ then the observed value is greater than what is predicted by the model. For our purposes, this is interpreted as the community having strength in this particular sector. If $N < \hat{N} \Rightarrow \hat{\varepsilon} < 0$ then we have the model predicting that the community should have a larger number of firms than observed. For our purposes, this is interpreted as the community having weakness in this particular sector.

For this study we use county sales tax data reported by the Wisconsin Department of Revenue at the county level.[4] Specifically, counties that have imposed the local option sales tax are included in this analysis. Because the data is reported at the county level, the trade area is defined to be the county. This implicit assumption may be reasonable for some goods and services and for some counties, but it is clearly not reasonable for most. Still, the analysis provides one set of information that can be used to develop a picture of the local retail and service markets across Wisconsin. But rather than using sales data as we recently did with a county-level Trade Area Analysis study (Deller, Kures and Ryan 2006), we are interest in the "count data" or the number of establishments (i.e., N above) that are subject to the sales tax.

The advantages of these data include an extensive coverage across a wide range of goods and services as well as inclusiveness of the number of firms in the data. Regardless of the narrowness of the tax code, specifically items that are taxable, if the firm offers for sale any good or service that is subject to the tax, they have a sales tax license and are counted in the data.

[4] For a detailed discussion of the Wisconsin sales tax see http://www.dor.state.wi.us/pubs/pb201.pdf particularly section X.

The weakness of the data is that firm count data does not account for firm size. A small "mom n' pop" grocery store is treated the same as a large supermarket. Another limitation is that the count data does not capture multi-product line stores. The most evident examples are the growing number of formats such as Wal-Mart Supercenters, Sears Grand Stores, and Super Targets that offer pharmaceuticals, groceries, hardware, automotive supplies and clothing. It is possible to have one community with a Wal-Mart that offers this wide range of goods next to a second community that has separate businesses that offer each good separately. From a market supply and demand perspective, both communities are the same, but they will appear very differently in the county data.

The categories included in this study are:

- Food Services & Drinking Places (Restaurants & Bars)
- Performing Arts, Spectator Sports & Related Industries
- Amusement, Gambling, Recreation Industries
- Automobiles & Other Motor Vehicles
- Gasoline Stations (including convenience stores with gas)
- Clothing & Accessories Stores
- Electronic & Appliance Stores
- Food & Beverage Stores
- Furniture & Home Furnishings Stores
- Health & Personal Care Stores
- Sporting Goods, Hobby, Book, & Music Stores
- General Merchandise Stores
- Other Store Retailers
- Hotels, Motels & Other Traveler Accommodations
- Banking, Insurance and Other Finance Activities
- Administrative & Support Services
- Health Care and Social Assistance Services
- Personal & Household Services
- Business Services
- Repair & Maintenance Services
- Professional Services
- Architectural, Engineering, & Related Services
- Computer System Services
- Scientific & Other Services
- Rental & Leasing Services

Thus there are 25 separate retail and service categories examined. While more detailed data in terms of firm types is preferable from a theoretical perspective, it can also become overwhelming in terms of data overload. The demand structure for stores that specialize in stereo equipment is fundamentally different than the demand structure for stores that specialize in major household appliances such as stoves, refrigerators and washing machines. But for reporting purposes the Wisconsin Department of Revenues groups these two different types of stores into the broad Electronic and Appliance Stores classification. This will lead to what can be called aggregation bias. Care must also be taken when we look at some of the specific categories, such as hotels and business services, where the demand structure is not driven by local household characteristics. The demand for architectural and engineering services, for example, is more a function of other types of businesses in the area and not necessarily the age structure of the community.

The next issue to be addressed is determining the set of right-hand-side variables to include in the analysis; which variables will explain the number of firms by type? Here we rely on economic theory and statistical methods to determine the final specification. Theory suggests that key groupings of variables should include measures of market size and income level and structure, as well as socioeconomic characteristics that might describe differences in tastes and preferences such as age structures and education levels.

The variables included in the analysis are:

- Number of Households[5]
- Number of Persons per Household
- Percent of the Population Under Age 17
- Percent of the Population Over Age 65
- Median Household income
- Per Capita Income
- Share of Total Income from Wages and Salary
- Gini Coefficient of Income Equality
- Percent of Households with Low Income (<$20,000)
- Percent of Households with High Income (>$100,000)
- Unemployment Rate
- Percent of Those Over 25 with at Least a HS Degree

[5] In the threshold literature the size of the market is commonly measured by population. We have elected to use number of households as an alternative. Preliminary analysis revealed that population and number of households are highly correlated and number of households tends to provide more stable results.

- Percent of Those over 25 with at Least a Bachelor's Degree

The next question is which specific variables are best suited to explain, or more precisely predict, the number of firms. Part of the limitations to this study is that our sample size is limited to the number of Wisconsin counties that have a local sales tax, a total of 55 counties.[6] Given a limited sample size it is not possible to include all possible right-hand-side variables at the same time because of a problem with degrees of freedom. A second problem is that many of these potential variables are correlated with each other introducing the problem of multicollinearity.

To address this collection of potential problems we employ a variable reduction method known as stepwise regression. What we are attempting to do is finding the "best" model from a number of possible models. The stepwise method is a uses a modification of the forward- and backward-selection technique. In the forward-selection method, variables are added one by one to the model, and the *F* statistic for a variable to be added must be significant at some preset level. After a variable is added, however, the stepwise method looks at all the variables already included in the model and deletes any variable that does not produce an *F* statistic significant at the preset level. Only after this check is made and the necessary deletions accomplished can another variable be added to the model. The stepwise process ends when none of the variables outside the model has an *F* statistic significant at the preset level and every variable in the model is significant at that level, or when the variable to be added to the model is the one just deleted from it. In essence we are allowing the data to determine which variables should be included as explanatory variables.

The stepwise regression method, however, has been subject to significant criticism. The purest criticism is that stepwise regression minimizes the role of theory in dictating what should be included. If the central thrust of the research is to test specific hypotheses, for example what impact does the widening income gap between the rich and poor have on the structure of local retail and service markets, then this criticism is legitimate. If, however, the thrust of the research is to uncover which variables, from a list suggested by theory, best explain the dependent variable, this criticism is not as disturbing. In the end these “variable reduction” approaches to statistical modeling is often dismissed as “data mining.”

A more appropriate criticism centers on the mechanics of the approach itself. As described above, significance levels of the *F* statistic is but one of many criteria that can be used for variable entry and exit. Others include changes in R^2 or adjusted R^2, the Mallows' C_p statistic,

[6] Milwaukee County has been removed from the analysis because of its relative size: it represents an “outlier” in the sample and introduces problems with the statistical modeling.

Cox and Snell's R^2, Hagle and Mitchell's pseudo R^2, Bayes Information Criterion (BIC), and the model chi-square test, also called the log-likelihood test. Which criteria to pick is purely up to the researcher and there are no theoretical rules to use one criteria over another. Some argue that the fatal flaw of stepwise regression is that for a given dataset and model, the final selection of variables should be at least close to the same across the different variable selection criteria. The final selection of variables should be consistent across the different selection criteria. This, unfortunately, is seldom the case; final model specification depends on the selection criteria used and there is no solid reason to use one criterion over another.

Despite these serious problems, for our purposes stepwise regression serves as a reasonable first approximation to the models outlined in equation (1). We use the traditional selection criteria of a critical *F* statistic and we elect a critical value of 85 percent confidence level. While this is a lower threshold than the traditional 95 percent level, we are open to having a general discussion of all possible variables that might help us understand the strengths and weaknesses of the retail and service markets across Wisconsin.

Before we begin our discussion of the stepwise regression results, let us briefly review some base statistics describing the sample of Wisconsin counties (Table 1). The classification with the largest number of firms is the "other store retailers" which includes specialty stores that do not fit into the other categories. The one classification that has the fewest is architectural, engineering and related service where the average county has only four of such firms, followed by professional services with only five firms for the average county. The categories that show the largest counts beyond the generic "catch all" classification of other retailer stores include personal and household services with an average of 401 firms, automotive and other motor vehicle retailers with an average of 364 firms, and business services with 262 firms. One must keep in mind that these data are drawn from sales tax data and many service firms may not be subject to the sales tax and hence are not included in the data.

The descriptive statistics for the pool of potential control variables are also included in Table 1. Number of households, our sole measure of market size, averages about 20,070 and range from 2,870 to 188,480. There is little variation in number of persons per household with an average of slightly more than 2.5 with a minimum of 2.19 and a maximum of 2.87. For the typical county in the sample, 23 and 26 percent of the population are between 0-17 and over the age of 65 respectively. Median household income and per capita income have large ranges with per capita income having a low of $18,500 and a high of $131,100 and an average of about $24,000. The Gini Coefficient of income distribution is included to explore the ramification of a widening income gap between the rich and the poor. Lower Gini Coefficients indicate more evenly distributed

income while a higher Coefficient suggest more income is concentrated in the hands of a few households. There is wide variation in income distribution across Wisconsin with one county reporting a Gini Coefficient of 0.34 and another is 0.55. The reader can review the remainder summary statistics.

Statistical Results

The explanatory power of the models is remarkably high given the cross-section nature of the data (Table 2). Of the 25 models 16 have R^2 greater than .9, or the models explain more than 90 percent of the variation in the number of firms. The most powerful model from an explanatory perspective is the Computer System Services model with an R^2 of .9715. Eight of the models have explanatory power between 80 and 80 percent as measured by the R^2 statistic. Only one sector, Hotels, Motels and Other Traveler Accommodations, has "poor" performance with an R^2 of .3741, or our "best fit" model given our step-wise regression approach explains 37 percent of the variation in hotels and motels. This latter result can be attributed to the "non-local" nature of these types of services.

Given our discussion below about the use of these models to make statements about the strengths and weaknesses of each sector for every county in the data, the relative levels of the R^2s are important. The percent of the variation in the dependent variable explained by the model, or the R^2, tells us how "tightly" the data fit the model. The "tighter" the model, the more confidence we can place on our estimates of strengths and weaknesses. A model where the data is "loose" suggests that there is something happening within the sector that the model is not explaining. Thus, is the observed weakness or strength actual or a product of a "poorly performing" model? Thus great care must be taken to ensure that the statistical model makes intuitive sense and confidence in the conclusions varies across models.

If we look at the significance levels, or statistical confidence levels, of the overall models based on the equation *F* statistic, each model is significant at or above the 95 percent level of confidence. The strongest model for an overall significance level is the Food and Beverage Stores model with an *F* statistic of 403.32 and the weakest is Hotels, Motels and Other Traveler Accommodations with an *F* statistics of 15.84. Other than the Accommodations model, which is the weakest performing model, all models perform above expectations. Given the relatively low R^2 and *F* statistic for the Accommodations model, greatest care must be taken when considering this sector.

There are two ways in which we can discuss the results of the models beyond the summary statistics. One way is to walk through each individual model, sector by sector. The second way

is to look at the performance of individual variables and the frequency of selection by the step-wise regression method as well as the direction of influence (positive or negative coefficients). We will employ a mixture of both but focus most of our discussion on the second approach.

The one variable that outperformed all other variables in terms of frequency of selection and level of significance as measured by the individual *t* statistics is the number of households, our measure of market size. Of the 25 models, number of household appears in 23 models and is significant above the 99 percent level of confidence in all 23 models. This strong result tells us that the notion of simple market thresholds measured by population, or in our case here number of households, provides a reasonable first approximation to market potential for certain types of firms. In other words the population thresholds provided by McConnon (1989) and Deller and Ryan (1996) are simple yet powerful tools in assessing market structure.

Because of this strong result, coupled with the idea of simple thresholds, we have produced a set of simple scatter plots where we plot number of firms on the vertical axis and number of households on the horizontal axis (Figures 1a through 1z). By introducing a simple "trend line" we get an idea of the nature of the threshold relationship. Notice that in every case, except two, there is a strong positive relationship, or the trend line, is upward sloping; in other words, markets with higher number of households can support more firms.[7] One can also look at the size of the estimated coefficient to gain insights into how sensitive the number of firms is to market size. For example, number of Personal and Household Services, with a coefficient of 9.07, is more sensitive to market size than Health Care and Social Assistance Services with a coefficient of 0.75. This suggests that as the market grows in terms of number of households, the number of firms in Personal and Household Services will grow much faster than the number of Health Care and Social Assistance firms.[8]

The next variable that is most commonly selected by the step-wise regression method is the share of total income that is derived from wages and salary. This variable is intended to capture the structure of income sources. Counties with higher levels of this simple ratio tend to be more dependent on employment for income as opposed to transfer payments, and other non-labor sources of income such as dividends, interest and rent. Of the 25 models, the share of total income from wages and salary enters 18 of the models, and the coefficient is positive in 17 of

[7] It is important to note that the trend line introduced in the scatter plots is not the same as those in the regression models.

[8] The observant reader will note that the size of the coefficient associated with number of households is directly tied to the average number of firms by type. Looking at Table 1, the classification with the highest sample mean, other retail stores, also has the largest coefficient on number of households.

those 18. The only model with this variable entering as negative is in the Performing Arts, Spectator Sports and Related Industries. The consistency of the importance of this variable couple with the positive coefficients suggests that sources of income should be further explored in future research.

Income inequality, as measured by the Gini Coefficient, is also found to be a strong predictor of number of firms. Recall that higher values of the Gini Coefficient are associated with larger gaps between high and low income households while smaller values suggest more even distribution of income. The Gini enters into 15 of the 25 models and the estimated coefficient is positive in each case. This implies that higher levels of income inequality tend to be associated with more firms. Consider, for example, there tends to be a larger number of Automobile and Other Motor Vehicles firms in counties that have higher level of income inequality.[9] Indeed, with a 10 percent increase in the Gini Coefficient, a large increase, we would expect to see almost a 50 percent increase in the number of firms of this type.[10] Why higher levels of income inequality are consistently associated with a larger number of retail and service firms is not readily clear. Again, the purpose of this applied research is *not* centered on hypothesis testing, but rather on uncovering patterns, and individual county strengths and weaknesses.[11]

To help provide more insight into the impact of income distribution on number of firms we also include the percent of households with annual income below $20,000 and above $100,000. Both measures enter six of the 25 models, and appear in only two simultaneously. One might expect (i.e., hypothesize) that a larger share of low income households would have a dampening (negative) affect on number of firms and this is true in five of the six models. Only in Sporting Goods, Hobby, Books and Music Stores classification is there a positive relationship. It is not clear why the data suggest this pattern.

---

[9] Within the literature it is widely accepted that auto supply stores tend to target lower to middle income areas. Higher income households have sufficient income to afford repairs.

[10] This estimated percentage increase is often reviewed to as an "elasticity" (ξ) which is computed as $\xi = \frac{\bar{x}}{\bar{y}} \times \frac{\partial y}{\partial x} = \frac{\bar{x}}{\bar{y}} \times \hat{\beta}$ where $\bar{x}$ and $\bar{y}$ are sample means of the right hand side variable of interest and the dependent variable respectively and $\hat{\beta}$ is the estimated regression parameter. If the estimated elasticity is, for example, .8, this can be interpreted as a 10 percent increase in the value of the independent variable (x) will result in an 8 percent increase in the dependent variable. In addition to computing the elasticity at the sample means, the interested reader can compute the elasticity for individual observations by using the data for the observation (county) of interest.

[11] Recall that hypothesis testing centers on relying on theory to predict the relationship between two or more variables. Theory tells us that x should influence y in some manner. The statistical analysis is then used to test that hypothesis.

The results for high income are more interesting with a mixture of positive and negative coefficients. For example, a higher concentration of high income households is associated with fewer Automobile and Other Motor Vehicles dealerships as well as Sporting Goods, Hobby, Book and Music Stores. When you combine the income distribution results on number of Sporting Goods, Hobby, Book and Music Stores the pattern becomes clear; these types of businesses are attracted to low income counties and repelled from high income ones.[12] The negative result on number of Banks, Insurance and Other Financial Services is surprising. One would think (hypothesize) that firms of these types would be drawn to areas with a large share of high income households. It may be the case that it is not the relative share, but the absolute number of high income households. Further research is required to further our understanding of this result.

There are three classifications that are associated with higher firm counts and these are Administrative and Support Services, Business Services and Scientific and Other Services. Although these results make sense, it may be the case that causation between high income share and these types of firms is reversed; is it the cases that the presence of these types of firms result or drive higher income levels?[13]

The age profiles, introduced to capture a narrow element of the tastes and preferences of the region (county), also help us understand the pattern of firm levels across Wisconsin counties. Percent of the population under 17 is negatively associated with six different classifications of businesses. The strongest negative associations are with Restaurants and Taverns, Car and Other Motor Vehicle dealerships, and Repair and Maintenance Services. The percent of the population over 65 is statistically significant in 12 of the 25 models and the estimated coefficient is positive in every case. Based simply on the size of the estimated coefficients, an aging population appears to have the biggest impact on Personal and Household Services, Business Services, and Furniture and Home Furnishings Stores. The result on Hotels and Other Lodging establishments is particularly interesting. Given other research results (Deller and Jensen 2005), percent of the population over 65 and retirement destination areas are correlated in Wisconsin,

---

[12] The potential of aggregation bias is potentially evident here. It is commonly believed that book stores tend to cluster in high income areas, opposite of the results found here. It may be the case that sporting good stores is overpowering book store affects. This is where finer classifications of store and service types make sense.

[13] All of our theoretical discussions have focused on firm location; hence our thinking about causation goes in one direction. If we were, however, thinking in terms of economic growth and development, such as what drives higher income levels, we may think in terms of certain types of industry clusters driving high income. Here the statistical causation direction would move in the opposite direction.

and retirement destination counties tend to be located in high tourism regions. What this suggests is that a higher percent of older persons may not "cause" a higher number of lodging accommodations, but rather there are other factors (e.g., high levels of natural amenities) that draw both lodging accommodations and retirees.

We also include education levels as another dimension that can help to describe variations in tastes and preferences of people within the region. Percent of the population over age 25 with at least a high school diploma is entered into only four models and is negative in each of the four. Percent of the population over age 25 with at least a Bachelor's degree enters into nine of the 25 models with a mixture of both positive and negative coefficients. Much like the result with a higher share of income households described above, a higher share of persons with a college degree has a strong dampening (negative) affect on the number of Car and Other Motor Vehicle dealerships. But at the same time a higher share of college educated people is also associated with a larger number of Hotels, Motels and Other Accommodations. This latter result is somewhat surprising and there does not appear to be a readily evident explanation for why we might expect this result. Higher education levels are also associated with fewer Repair and Maintenance Service firms as well as fewer Computer System Services. While the former result on Repair and Maintenance Service firms makes intuitive sense, the result on Computer Services does not. Indeed, if Computer Services is part of the "new" high tech economy and education is presumed to be integral to that "new" economy, this result is counter-intuitive. Clearly, the relationship between the "new economy", education, and computer services is more complex than what is captured in this simple firm count model.

The one set of economic indicators that performed surprisingly poor are the two income measures, per capita income and median household income. Theory suggests that aggregate demand, the key component of revenue maximizing firm location theory, drives the patterns we observe and aggregate demand is determined by market size and ability to pay, or income. Per capita income enters into only two models and median household income enters only one model. Based on our analysis it appears that income distribution is more important than income levels in explaining firm counts. Why this is the case is not readily clear and warrants further research.

Our final two measures are the unemployment rate and number of persons per household. The unemployment rate has been shown in other studies to be a powerful predictor of retail and service sales levels, but given the Wisconsin data it does not appear to be a predictor of firm count data. It may be the case that sales levels are more reflective of short-term economic conditions whereas firm counts are more reflective of long-term conditions. One could think in terms of asset fixity in a long- versus short-term perspective. Firm investments in facilities,

operational equipment and inventories are often viewed as long-term; firms will not close then reopen through short-term fluctuations. Firms will ride-out short-term downturns in the economy. Thus, while unemployment rates help explains sales levels, it does not help us understand firm counts.[14]

Number of persons per household enters with a positive coefficient in five of the 25 models and negative in one model. Historically, number of persons per household served as a proxy for families with young children. Today's social dynamics makes this interpretation overly simplistic; hence greater care must be taken when thinking about this particular socioeconomic variable. The classifications of businesses that have a positive relationship with household size includes Furniture and Home Furnishings Stores, General Merchandise Stores, Administrative and Support Services, Personal, Household and Business Services. Interestingly, larger household sizes are associated with few numbers of Performing Arts, Spectator Sports and Related Industries.

As we mentioned in the introductory comments to this section of the study, there are two ways to review the statistical results; the first is to describe the role of individual variables, as we have just done, the second is to review the modeling results across business classifications. Given that we are looking at 25 separate business classifications, a detailed discussion of each classification would be a lengthy undertaking. Rather, we will select a handful of the more interesting classifications to further discussion.

One of the fastest growing classifications is the Food Services and Drinking Places (restaurants and taverns) sector. As the dynamics of family life has changed over the years, the demand for restaurants has grown rapidly and in Wisconsin taverns have acted as social gathering places for generations. Our model explains 96.3 percent of the variation in the number of restaurants and taverns and the overall equation is statistically significant above the 99 percent level of confidence (*F* statistic equals 261.43). Beyond the intercept term, five of the possible 13 explanatory enter into the model. As with almost all of the models, number of households in the county is an important predictor of the number of restaurants and taverns. If we compute an elasticity (see footnote number nine above) we find that a ten percent increase in the number of households will see a six percent increase in the number of Food Services and Drinking Places. Looking at the simple trend line outlined in Figure 1a, we see that there is a fairly "tight fit" (i.e.,

[14] The discussion here treats unemployment as a short-term phenomenon, as the economy fluctuates, the unemployment fluctuates. The idea of persistently high unemployment is not considered and may be a better measure when looking at firm count data. Persistent unemployment could be measured as a moving five year average.

high R^2) between the trend line and the observed data points. This result again gives support to the idea of simple market thresholds as a reasonable first indicator of market potential.

Percent of the population under age 17 has a negative association with the number of restaurants and taverns in the county. This is somewhat surprising because there is a general perception that as the number of single parent and dual wage earning families grows, the demand for prepared meals and services offered by restaurants increases. Thus we should expect a positive relationship between percent of the population under age 17 and the number of restaurants (perhaps not taverns), but we find the opposite. It may be the case that our measure is not capturing the changing dynamics of the family. On the other hand, it may be that the changing family dynamics is affecting the type of products sold in grocery stores and not in the number of restaurants in the region. It is more likely that households with a large number of children will influence the concept of the restaurant (i.e., fast-food, fast-casual, formal dining, etc.) rather than the number of restaurants. Given our simple model, we can not draw any stronger conclusions.

The remaining three variables that are introduced into the Food Services and Drinking Places sector include share of total income from wages and salary, the unemployment rate, and the Gini Coefficient of income equality. Higher values of each of these variables are associated with a larger number of restaurants and taverns. Income levels do not seem to influence the number of restaurants and taverns nor does education levels.

Next consider the number of Food and Beverage Stores within the region. Again, number of households is a strong predictor of this classification of businesses (Figure 1h). The estimated elasticity suggests that a ten percent increase in the number of households, the number of Food and Beverage Stores will increase by 5.6 percent. The percent of the population over age 65 is also positively associated with the number of grocery and beverage stores, although at a low level of statistical significance. The only other variable that was introduced is the percent of households with income below $20,000 and the estimated coefficient is negative. Given simple neoclassical economic theory this latter result is expected.

The model that performs the weakest is Hotels, Motels and Other Traveler Accommodations. As noted above the model explains only 37.4 percent of the variation in the number of establishments and the overall significance of the model is the weakest of all 25 models (*F* statistic equal 15.84). Unlike almost all the other models, the number of households has no influence on the number of Hotels, Motels and Other Traveler Accommodations. Indeed, the simple scatter plot (Figure 1n) shows that there is little if any relationship between market size

and number of firms.[15] The role of the percent of the population of 65 and its positive influence on the number of Traveler Accommodations is perhaps an indirect relationship. As discussed above, it may be that migrating retirees are attracted to high tourism areas and in Wisconsin those areas are closely tied to high natural amenities. We also find that counties that have a highly educated population, as measured by the percent of those over age 25 with at least a Bachelor's degree, tend to have a larger number of Hotels, Motels and Other Traveler Accommodations. Why education levels should influence the number of accommodations is not clear and this result may be a statistical anomaly.[16]

The statistical results presented here have provided us with several insights into why some regions have a large number of certain types of retail and service firms while others have a small number. First and foremost, the absolute size of the market, as measured by the number of households, is the strongest predictor of the number of firms. The large *t* statistics coupled with the visual evidence presented in the scatter plots supports this conclusion. Second, the absolute level of income, whether measured by per capita income or median household income, is not nearly as important as income distribution. Interestingly, the more uneven the distribution of income, the more firms of a range of types is likely to be present. Also, the source of income seems to play a roll. Third, age and education profiles play a role in a few classifications of businesses examined.

Market Strengths and Weaknesses

One of the primary reasons for undertaking this applied research project has been to identify the strengths and weaknesses of each county contained in the sample across all 25 business classifications. As outlined in the methods section of this study we are specifically focusing on the error term from the regression models. One way to visualize this approach is to consider one of the scatter plots presented in Figures 1a through 1z. The trend line provides us with the predicted, or expected, number of firms for a given number of households. The actual number of establishments then lines on, above or below the trend line. If the observed number of firms is the same as the expected, or predicted, then the error term is equal to zero and the county is

[15] There are two ways to think about the simple scatter plot (Figure 1n). The first is the relative "flatness" of the trend line points to the statistical insignificance of the relationship. The second is the handful of "outliners" that are clearly heavy tourism dependent areas. This latter problem of "outliers" may introduce statistical problems into the regression analysis. Recall, this is the very reason we removed Milwaukee County from our sample.

[16] Recall that this is one of the fundamental criticisms of step-wise regression; the empirical results may have no theoretical justification and as such are no more than a statistical fluke. The idea of confusing statistical relations with theoretical causation goes back to an infamous study that linked the rain fall in Australia to the performance of the NY Stock Exchange. The point being that statistical relationships do not necessarily lead to meaningful causation.

performing on par with what we would expect. If the observed number of firms is below the trend line, then the difference between the observed and predicted will be negative. Subsequently, the sector is not performing as well as expected and the sector can be considered a weakness. On the other hand, if the observed value is above the trend line, the sector is considered a strength. The observed, predicted and error for all the counties contained in the sample are reported for each of the 25 business classifications in Table 3. All predicted values are based on the regression models reported in Table 2 and discussed at length in the above section of the study.

The policy objective of this approach is to identify retail and service sectors for "targeted" economic development and growth activities. We could offer a simple "decision rule" for which type of firms to target, such as sectors that are identified as "under performing" or the observed number of firms is less than the predicted level (i.e., a negative error term). But, as we will see, there are several cases where the level of under performance is relatively small. These "narrow" margins of error raise an interesting and important question; how large should the error be on the negative side (i.e., weakness) be before the industry is targeted for further growth and development efforts? We could develop a statistical test by building a confidence interval around the predicted level, and if the under performance is outside the confidence interval, then the industry should be targeted.[17] Developing and reporting such a confidence interval for every county in the sample is beyond the scope of this particular study and could be the subject of future work.

A more *ad hoc* approach might be to set an arbitrary interval of say plus or minus ten percent of the predicted value. For example, if the predicted value is 50 firms, then this *ad hoc* rule would be plus or minus ten percent or five $(50 \pm 5 \Rightarrow 55:45)$ so if the observed value is outside that range, then one could conclude that the industry could be targeted. If the observed value is within that range, then the predicted value is "sufficiently" close to the observed to conclude that the county is performing as expected. What makes this approach *ad hoc* is that the level of ten percent is arbitrary; why not five or twenty percent? For ease of discussion below we will not expand on this idea and leave the interpretation of the whether or not the observed error is sufficiently large up to the reader.

Much like the discussion of the statistical modeling results above, there is a vast amount of information provided in Table 3 and a thorough discussion of all the results would yield pages of

[17] To compute a confidence interval we would ask what the statistical distribution is around our estimated or predicted number of firms for some level of confidence, such as the 95 percent level. The specific formula is $\hat{y} \pm (z \times \sigma)$ where $\hat{y}$ is the predicted value, z is the level of confidence (for a 95 percent level, z is equal to 1.96), and σ is the standard error of the regression equation.

narrative. Therefore, we will select a handful of counties to illustrate some of the means in which these results can be interpreted. Jefferson and Crawford represent two counties that are comparable to a wide range of Wisconsin counties. Jefferson County has a population of about 78,000 persons composed of several smaller cities and is located between the fast growing western suburbs of Milwaukee to the east of the county and Dane County to the west. Jefferson County has experienced strong growth in population, employment and income as well as growth in the retail and service sectors. Crawford County, on the other hand is a more rural county with a population of about 17,000 persons, located in the Driftless Region of Wisconsin it is a traditionally agricultural area that is experiencing a slow transition to a more tourist based economy.

Consider first the number of Food Services and Drinking Places (restaurants and taverns). The statistical model presented in Table 2 suggests that Crawford County should have 97 restaurants and taverns and Jefferson should have 238. When compared to the observed Crawford County has 76 restaurants and taverns which is 21 firms below what we would expect to see. Given the logic of our approach, Food Services and Drinking Places is a weakness for Crawford County and there may be opportunities for growth in this sector. Jefferson County has 258 Food Services and Drinking Places which is 20 firms higher than predicted by our statistical model. Again given the logic of our approach, restaurants and taverns is a strength sector for Jefferson County.

If we look at Amusement, Gambling and Recreational Industries we see that the statistical model predicts that Jefferson County should have 38 firms and indeed it has 38 firms. The error term in this case is zero and the County is performing exactly on par with what we would expect. For Crawford County, the model predicts that there should be 17 firms that fall into the classification of Amusement, Gambling and Recreational Industries, but we observe 10 actual firms. The resulting error term is -7, or the County has seven fewer firms then expected and could be considered a weakness of the County.

The Automotive and Other Motor Vehicles sector is also a strength for Jefferson County and a weakness for Crawford County given our statistical model. For Jefferson County the model predicts that there should be 546 car and other motor vehicle dealerships but we observe 640, or 94 businesses more than we expect. This is clearly a strong sector for Jefferson County. The model predicts that Crawford County should have 235 such firms, but we observe 206, or 26 few firms than expected. Again given the logic of our modeling, this represents a weakness and a potential area of expansion for Crawford County.

If we look at the number of Gasoline Stations (including convenience stores with gas), Jefferson County is predicted to have 50 firms, but in reality has 45 Gasoline Stations or five fewer than expected. Crawford County is predicted to have 27 Gasoline Stations and has an observed 21 or six fewer than expected. If we look at Food and Beverage Stores the predicted and observed value for Crawford County is 27 and 29, respectively and 70 and 71 for Jefferson, respectively. In both of these classifications of businesses the error is relatively small. The purchaser buys convenience goods and services (such as groceries, gasoline) with a minimal amount of effort and usually at the most convenient and accessible store. Convenience goods or services typically have a small unit value; purchases are frequent; they are made soon after the idea of the purchase enters the buyer's mind.[18] Research suggests that these types of good and service markets are "efficient" in the sense that predicted and observed values tend to be close or errors are small.

If we look at Clothing and Accessories Stores we see that Crawford County does better than we would expect given the statistical modeling results; the model predicts that there should be 49 stores but there are actually 54 stores in the County. For Jefferson County the strength of the Clothing and Accessories Stores is even more pronounced where the model predicts 95 stores within this classification but we observe 122 stores, or 27 more than expected. The strength in Jefferson County could be attributed to the Johnson Creek outlet mall development.

The one type of store classification that is widely used as an example of comparison goods, or goods and services purchased only after comparing price, quality, and type among stores and places, is Furniture and Home Furnishings Stores. The theory suggests that these types of firms require large markets to support their cost structures and the comparison shopping nature of the good will tend to drive these firms to agglomerate or cluster in geographically central locations, such as a Madison, Eau Claire or Green Bay. Thus, the findings for Crawford County support this idea where the observed number of stores of this type is smaller than the predicted level by 20 firms. Jefferson County, on the other hand, has some 81 more stores of this type than we would expect given the statistical model. Clearly this is a strength for Jefferson County and it raises the question of if it is a strength that can be built upon. Interestingly, according to the theory, Dane County should have a strong "surplus" of Furniture and Home Furnishings Stores, but we find that the predicted is above the observed, the opposite conclusion than we would expect given the

[18] Intermediate goods posses characteristics of both shopping and convenience goods; the purchaser will spend some time shopping, although the time is minimal and typically the purchase is made close to home. Examples of intermediate goods are drugs, hardware items, banking and dry cleaning services. The purchaser buys comparison goods (furniture, cars, TVs) and services only after comparing price, quality, and type among stores and places.

theory. Despite the perception that Dane County and Madison in particular is a strong retail and service hub, this result suggests that there could be a weakness that could be addressed.

When we examine the services sectors, for brevity we will simply review the strengths and weaknesses for both of our representative counties. In Crawford County we see weaknesses in Banking, Insurance and Other Finance Activities ($\hat{\varepsilon}$ = -8), Administrative and Support Services ($\hat{\varepsilon}$ = -10), Health Care and Social Assistance Services ($\hat{\varepsilon}$ = -4), Business Services ($\hat{\varepsilon}$ = -11), Repair and Maintenance Services ($\hat{\varepsilon}$ = -29), Computer System Services ($\hat{\varepsilon}$ = -16), and finally Rental and Leasing Services ($\hat{\varepsilon}$ = -15). There is a strength, or surplus, in Personal and Household Services ($\hat{\varepsilon}$ = 22) and a weak strength in Professional Services ($\hat{\varepsilon}$ = 1). Jefferson County, on the other hand, tends to experience strengths in many of the service sectors. Jefferson County reveals strengths in Banking, Insurance and Other Finance Activities ($\hat{\varepsilon}$ = 4), Administrative and Support Services ($\hat{\varepsilon}$ = 22), both Personal and Household ($\hat{\varepsilon}$ = 79) and Business ($\hat{\varepsilon}$ = 78) Services, Repair and Maintenance Services ($\hat{\varepsilon}$ = 58), Computer System Services ($\hat{\varepsilon}$ = 24), Scientific and Other Services ($\hat{\varepsilon}$ = 8), and Rental and Leasing Services ($\hat{\varepsilon}$ = 27). Jefferson County has only a small handful of weaknesses in the service sectors including Health Care and Social Assistance Services ($\hat{\varepsilon}$ = -4) and Architectural, Engineering and Related Services ($\hat{\varepsilon}$ = -4),

When interpreting these results it is vital to think about whether policies should be aimed at addressing weaknesses or building upon strengths. In the long-term successful policies will address both but short-term policies may best be focused on a limited, or targeted, set of industries. In the end the community development practitioner must combine information from a range of sources. If that information “triangulates” in a particular direction, then the research foundation has been established. In the end, there is a certain element of art in interpreting the results and crafting policies for the right businesses for the community.

Conclusions

The applied research presented in this study provides the community economic development practitioner with two sets of information; (1) a family of statistical models that provide insights into the drivers of firm levels for retail and service sectors and (2) a set of measures indicating the strengths and weaknesses of individual retail and service sectors for all of the Wisconsin counties contained in the sample. Using traditional firm location theory we combine several lines of research, specifically market threshold analysis and industry targeting methods.

The statistical analysis provides three generalizations: (1) market size, as measured by number of households is the single strongest predictor of firm counts; (2) income distribution is more important to firm counts than income levels; (3) there is significant variation in the socioeconomic drivers of firm activity levels across firm classifications. The first result lends strong support to the simply population threshold approach to market analysis. The second result is somewhat unexpected and warrants further analysis given the widening of the income distribution over the past twenty years. The final result tells us that some counties could specialize in certain types of retail and service firms (e.g., tourism) have will have a difficult time supporting others.

This particular applied research study should be viewed as one of a series of studies looking at the drivers of retail and service patterns across Wisconsin as well as providing indicators of the strengths and weaknesses of those sectors. This work lays out several possible future research directions. First, the county is an arbitrary unit of analysis and is used in this study simply because the data is widely available at the county level. Future work must consider sub-county units of analysis such as the municipality. Second, theory tells us that markets are not independent in a spatial sense: what is located in one county will influence the neighboring counties. Future work must take this "spatial dependency" into consideration. Third, the idea of multipurpose shopping trips suggests that certain retail and service firms will tend to cluster together. Also known as economies of scope in the retail and service sectors, firms of different types (as defined by the NAICS system the data are reported) will group together. In other words, the presence of one group of businesses will increase the likelihood of other types of businesses also be located in close proximity. Future work must acknowledge these clustering or agglomeration affects to increase the efficiency of our models.
